Predicting Death

An Empirical Evaluation of Predictive Tools for Mortality

George C. M. Siontis, MD; Ioanna Tzoulaki, PhD; John P. A. Ioannidis, MD, DSc

Background: The ability to predict death is crucial in medicine, and many relevant prognostic tools have been developed for application in diverse settings. We aimed to evaluate the discriminating performance of predictive tools for death and the variability in this performance across different clinical conditions and studies.

Methods: We used Medline to identify studies published in 2009 that assessed the accuracy (based on the area under the receiver operating characteristic curve [AUC]) of validated tools for predicting all-cause mortality. For tools where accuracy was reported in 4 or more assessments, we calculated summary accuracy measures. Characteristics of studies of the predictive tools were evaluated to determine if they were associated with the reported accuracy of the tool.

Results: A total of 94 eligible studies provided data on 240 assessments of 118 predictive tools. The AUC ranged from 0.43 to 0.98 (median [interquartile range], 0.77 [0.71-0.83]), with only 23 of the assessments reporting excellent discrimination (10%) (AUC, >0.90). For 10 tools, accuracy was reported in 4 or more assessments; only 1 tool had a summary AUC exceeding 0.80. Established tools showed large heterogeneity in their performance across different cohorts (I² range, 68%-95%). Reported AUC was higher for tools published in journals with lower impact factor (P = .01), with larger sample size (P = .01), and for those that aimed to predict mortality among the highest-risk patients (P = .002) and among children (P < .001).

Conclusions: Most tools designed to predict mortality have only modest accuracy, and there is large variability across various diseases and populations. Most proposed tools do not have documented clinical utility.

pared across different tools, while relative risk metrics depend on the unit to which they are expressed and cannot directly compare predictive tools expressed for different units of measurement.11

We excluded studies that only had data on the development of a new predictive tool or validated the predictive tool in the same cohort where it was developed because new, nonvalidated predictive tools are likely to have inflated estimates of accuracy.12-15 We also excluded articles that did not provide primary data (eg, reviews) and studies where death was part of a composite outcome or was determined as cause-specific (rather than all-cause) mortality.

When there were several eligible predictive tools and/or they assessed the ability to predict death at different lengths of follow-up in the same cohort, each proposed predictive tool and each time of follow-up assessment was included separately. For example, one study examined 2 predictive tools (Multidimensional Prognostic Index [MPI] and Pneumonia Severity Index [PSI]) for a total of 6 assessments at 3 different follow-up periods (1, 6, and 12 months) (see reference S47 in eReferences).

DATA EXTRACTION

The full text of the eligible studies and any supplementary materials were scrutinized to extract information on study design, characteristics of the cohort (prevalence of specific diseases), characteristics of the predictive tool and data on calibration,13 reclassification,16-18 and accuracy. For each study, we recorded the journal impact factor per the Institute for Scientific Information.19 Calibration examines whether the risk prediction is equally good for patients at different levels of risk or there is a lack of fit. Reclassification analysis by means of the net reclassification improvement and the integrated discrimination index.

RESULTS

Overall 544 items were retrieved from Medline, of which 235 were reviewed in full text. Of those, 94 articles (eReferences) were deemed eligible (eFigure). The interrater agreement (between G.C.M.S. and I.T.) for the selection of the eligible studies had k value of 0.86.

These 94 manuscripts presented data on 240 assessments (224 multivariate models and 16 single predictors) of the accuracy of 118 predictive tools. Characteristics of studies and predictive tool assessments are listed in eTable 1. Most of the studies were performed in the United States or Europe, had a prospective cohort design, and pertained to acute disease conditions. Cardiovascular, critical-illness, infectious, gastroenterology-related, and malignant diseases accounted for 83% of the cohorts, but many other diseases were also assessed (eTables 1, 2, and 3). The median (IQR) sample size for the assessments was 502 (185-2016); the median (IQR) number of deaths was 71 (32-157); the median (IQR) proportion of deaths was 14% (5%-29%); and the median (IQR) death rate was 13% (4%-44%) per month. Among the whole data set (94 studies), in only 1 study (S85 in eReferences) did the investigators review and abstract patient data blinded to patients’ hospital course and clinical status (eTable 1). For 78 studies, the percentage of losses to follow-up was available (70 studies reported no losses, while for the rest loss was generally low (median [IQR] loss to follow-up, 3.5% [1.25%-10.25%]).

PREDICTIVE TOOLS

Overall, 110 different predictive models and 8 different predictors were examined in the 240 assessments. The most commonly evaluated models included the Acute Physiology And Chronic Health Evaluation (APACHE) II model (n=19) and the MELD score (Model for End-Stage Liver Disease) (n=17) (Table 1). The predictive models included a wide range of variables (eTable 2). The number of variables in the models ranged from 2 to 30, and the median (IQR) number was 6 (4-12). All of the identified single predictors were biomarkers (eTable 3).

CALIBRATION AND RECLASSIFICATION

Calibration of the examined predictive tools was examined in fewer than half of the included studies (n=45; 48%), mainly by using the Hosmer-Lemeshow statistic (n=35; 78%) and observed/predicted ratio (n=5; 11%). Results were available in 44 studies (105 predictive tool assessments), indicating lack of fit for 8 studies (17 predictive tools).

Only 1 study (S83 in eReferences) examined reclassification analysis by means of the net reclassification improvement and the integrated discrimination index. This study investigated the added predictive value of radiographic ascites over and above the MELD-Na score in patients with cirrhosis.
A total of 95 of the AUC values were higher than 0.80 (very good discrimination) (40%), but only 23 were higher than 0.90 (excellent discrimination) (10%).

The AUC data for all predictive tools with 2 or more assessments are listed in Table 1. For each of these 34 tools, the range of AUC estimates was large, sometimes spanning the spectrum from inaccurate to excellent accuracy. The median AUC values suggested modest accuracy. For only 2 predictive tools (Clinical Risk Index for Babies [CRIB] II [S25 and S27 in eReferences] and Pediatric death prediction model [S92 in eReferences]), the median AUC value suggested excellent accuracy (AUC, 0.91 and 0.92, respectively), but this was based on only 2 assessments of each tool. Four or more assessments of the accuracy of a predictive tool were available for only 9 tools (APACHE, MELD, SOFA [Sequential Organ Failure Assessment], CTP [Child-Turcotte-Pugh], SAPS [Simplified Acute Physiology Score] II, PSI, CLIP [Cancer of the Liver Italian Program], CURB-65 [confusion–blood urea nitrogen–respiratory rate–blood pressure–age ≥65 years], JIS [Japan Integrated Staging]) and 1 biomarker (NT-pro-BNP [N-terminal-pro-B-type natriuretic peptide]). Using random effects meta-analysis, we found that the summary AUC estimates for these 10 tools ranged between 0.73 and 0.84 (Figure 2). For each of the 9 multivariable tools, there was marked heterogeneity of AUC values across diverse settings and studies (heterogeneity I² estimates in AUC ranged from 68% to 95%). The 95% CIs of the I² were also consistent with a large or very large heterogeneity. For NT-pro-BNP, the I² estimate was 25%. Meta-analyses retaining only the longest follow-up assessment when several follow-up assessments were available from the same study showed similar results (all changes in summary AUC estimates were <5% compared with the primary analysis including all data).

CORRELATES OF ACCURACY

As listed in Table 2, predictive tools published in journals of lower impact factor had higher reported AUC estimates than those published in journals of higher impact factor. Predictive tools were more accurate in predicting mortality when a smaller proportion of study participants died. The AUC values were also more accurate in pediatric than in adult populations. Finally, studies with larger sample size tended to have higher AUC values than smaller studies.

There was no evidence that study design (retrospective vs prospective), area of origin, disease status, clinical condition examined, death rate per month, loss to follow-up, or number of variables included in the predictive tool were associated with the AUC values (data not shown).

Our systematic evaluation of a large number of seemingly well-validated predictive tools reported in the recent literature shows that these tools are not very accurate and that there is wide variation in their predictive accuracy for death. Most of the tools included in our analy-
To obtain the results of AUC and 95% CIs are provided using random effects (n=number of assessments) with 95% confidence intervals (CIs). Summary for predictive tools that were examined in 4 or more assessments.

For a proposed predictive tool to be useful in clinical practice, there are several prerequisites. The tool must be validated in populations other than the one in which it was developed; it should be reproducible; and it should have good accuracy and calibration. Such a predictive tool can make accurate predictions in diverse settings across the range of both low- and high-risk patients. Few tools for predicting risk of death currently fit these criteria. Even tools that meet these criteria may not necessarily result in improvement in patient management and outcomes. This depends on whether effective, feasible interventions are available, the use of which is based on accurate knowledge of patient risk. However, reclassification, the ability to reclassify individuals into more appropriate risk categories where different actions/interventions might be indicated, is almost never assessed in the current literature of death prediction. Moreover, randomized trials on the use of predictive models, the ultimate proof of benefit, are few and difficult to conduct. Finally, clinicians are unlikely to use complex tools that require collection of extensive information, including data derived from expensive tests. It is possible that other predictive tools, based on far more limited clinical data, may perform equally well or better. In our empirical evaluation, models with more variables did not seem to perform clearly better than models with few variables.

Some characteristics of predictive tools were significantly associated with higher AUC estimates. For example, tools performed better when they tried to predict death only for the highest-risk patients. Excellent

### Footnotes

a Number of the predictive tools related to the respective extracted variable.
b One-way analysis of variance for categorical variables (study population) and Spearman correlation coefficient for continuous variables (impact factor, sample size, and proportion of death).
performance was seen in a small number of pediatric tools, while performance was substantially worse in predictive tools for adults. Larger studies tended to have slightly higher AUC estimates. These associations are exploratory and should be viewed with caution.

In our evaluation we focused on validated tools. However, even for some of the most widely applied predictive tools (such as APACHE II, MELD score, and SAPS II), we found great within-tool variability in accuracy across different studies and clinical settings. The observed variation of the accuracy for the same predictive tool may be partly ascribed to the selective analysis and reporting of studies of predictive tools that may lead to exaggerated results of predictive discrimination in some studies. Efforts at standardization of reporting are important in this regard. The inverse correlation between journal impact factor and reported AUC that we observed may represent lower methodologic quality with spuriously high reported predictive performance in some articles published in journals with low impact factor. Moreover, studies often test predictive tools in populations that are very different than the one the model was developed for and for a wide range of outcomes. This may further contribute to the variability seen in their discriminatory performance.

Some limitations should be mentioned. Our empirical assessment was restricted to studies published during a single year. An effort to appraise the entire predictive literature would be a task requiring extensive international effort by hundreds of researchers, much as the Cochrane Collaboration has done for clinical trials. Moreover, we included only studies dealing with prediction of all-cause death, and we did not evaluate the accuracy of tools designed to predict other outcomes. However, death from any cause is a common outcome with great clinical impact, and it is possible to standardize unambiguously. Finally, we considered only predictive studies that assessed accuracy using the AUC. However, AUC is not the only metric to assess predictive ability, and like any single metric, it can have limitations. For example, the AUC does not provide information on the actual predicted probabilities, and it does not convey the exact risk distribution in the respective study population. Also, improvements in AUC are more difficult in the high-range values than when AUC is closer to 0.50. Nevertheless, AUC is a very useful metric and is the most widely used standardized metric in the predictive literature.

Given the very wide variability in the AUC, even for the same predictive tool, we believe that systematic efforts are needed to organize and synthesize the predictive literature, such as those proposed by the Cochrane Prognosis Methods Group. Such efforts are needed to enhance the evidence derived from predictive research and to establish standard methods for developing, evaluating, reporting, and eventually adopting new predictive tools in clinical practice. Clinicians should be cautious about adopting new, initially promising predictive tools, especially complex ones based on expensive measurements that have not been extensively validated and shown to be consistently useful in practice.
